

Project 1 Final Design Document

Fang Zhang,
Qiushi Huang,
Zhengyang Song,
Zhaopeng Yan

April 14, 2015

Notice: the different part of initial and final design document has been processed automatically by command *latexdiff*, which leads to green lines between the different parts. Also, we have a new section named *Test Cases* to describe all the test cases we have implemented so far.

1 Join

1.1 Design

When a thread A calls B.join(), to wait B finishes, it adds itself to B's waitqueue and sleeps. After B finishes, B will wake up all the threads in the waitqueue so that they can continue running.

1.2 Variables and functions

1.KThread::waitqueue: private variable in KThread, save the threads which are waiting the thread to finish.

2.KThread::join(): When the current thread wants to wait another thread B to finish, it will call B.join. The function will add the current thread to the thread's waitqueue and sleep if the thread doesn't finish.

3.KThread::finish(): when a thread finishes, it will call this function to wake up all the threads waiting it. It will let the threads in waitqueue call ready() to add to the ready queue.

1.3 Pseudo-code

Algorithm 1: KThread::join

```
1  disable interrupt
2  if this.statues  $\neq$  statusFinished then
3    |   add current thread to waitqueue
4    |   sleep()
5  restore interrupt
```

Algorithm 2: KThread::finish

```
1 the same as the existing code
2 if waitqueue isn't empty then
3   for every thread i in waitqueue do
4     i.ready()
5 sleep()
```

1.4 Correctness constraints

- 1.If A joins B, A will never be scheduled before B finished.
- 2.If A joins B, A will continue running after B finished.

1.5 test strategy

1. Fork a thread which output when it begins and ends and let the current thread join it. Test whether the join function works.
2. Fork several threads and each thread joins the thread forked before it. Test whether the join works when there are threads join each other.
3. Fork a thread and let the current thread fork it two times. Test whether when a thread joins a thread which is already finished can work.

2 Condition variable

2.1 Design

We need to implement `sleep()`, `wake()` and `wakeAll()` methods for this question. For we are forbidden to use semaphore as what has been done in `Condition.java`. We need to find another way around.

To do this, we also need a ~~wait-queue~~ `waitQueue` to record all the threads that are waiting this condition variable by now. Rather than placing a corresponding semaphore in the queue, we put the corresponding thread itself.

2.2 Variables and functions

For `waitAll()`, it is just all the same as before. We call `wake()` for all the elements in the wait queue. Notice that we need to disable interrupt before and enable interrupt after.

For `sleep()`, we just put the current thread to the ~~wait-queue~~ `waitQueue`, and make it sleep. In order to guarantee atomic condition, we disable interrupt and acquire the lock ~~and-disable-interrupt~~ before operation while ~~enable-interrupt~~ and-release the lock and enable interrupt after operation. (order matters)

For `wake()`, we examine whether the ~~wait-queue~~ `waitQueue` is empty. If not, just remove the first thread from ~~wait-queue~~ `waitQueue` and put it into the ~~ready-queue~~ `readyQueue`. Note that before the operation we disable the interrupt before and enable the interrupt after.

Algorithm 3: Condition::sleep

```
1 disable interrupt
2 release the lock
3 disable interrupt add current thread to wait queue
4 make current thread sleep
5 enable interrupt acquire the lock
6 enable interrupt
```

Algorithm 4: Condition::wake

```
1 if wait queue is not empty then
2   disable interrupt;
3   remove first element;
4   put it into ready queue;
5   enable interrupt
```

2.3 Pseudo-code

2.4 Correctness Constrains

- For any time, only one thread is running
- When one thread sleeps, it will not wake until some thread wakes it

2.5 Test strategy

- init a lock, and init a condition variable using the lock
- fork several thread, call sleep() for all, test whether all threads go to sleep
- call wake() to test whether one of the sleeping threads will awake
- call wakeAll() to test whether all the sleeping threads will awake

3 Alarm

3.1 Design

We need to overwrite the waitUntil(long x) method in the Alarm class with no busy waiting strategy. The aim of this method is to suspend the execution until

Algorithm 5: Condition::wakeAll

```
1 disable interrupt;
2 while wait queue not empty do
3   wake()
4 enable interrupt;
```

time has been $\text{now} + x$. When the time is right, we just put it into the ready queue rather than let it run immediately.

So we can add a wait queue to Alarm class, every time `waitUntil` is called, we just compute the corresponding wake time of that thread, and put the thread together with the wake time into the wait queue (To realize this, we make a new class named `AlarmedThread`, this is also comparable in order to use `PriorityQueue` based on the `timeToWake`). Then let the thread sleep (before and after we disable and enable interrupt). Whenever there is a timer interrupt, we check the wait queue to see whether there is any thread is due (Using `PriorityQueue`, we just exam the first thread). If so, we just put it into the ready queue.

3.2 Pseudo-code

Algorithm 6: Alarm::`timerInterrupt`

```

1 disable interrupt get current time;
2 for i in wait queue do
3   if wake time of i  $\neq$  current time then
4     | put i into ready queue
5   | enable interrupt

```

Algorithm 7: Alarm::`waitUntil(x)`

```

1 get current time;
2 wake time = current time + x;
3 put current thread together with wake time new AlarmedThread using
  parameter of current thread and time to wake put the AlarmedThread
  into wait queue;
4 make current thread sleep

```

3.3 Correctness Constrains

- The thread will not run until wake time
- When it beyonds the wake time, the thread will be ~~put into the ready queue~~ woken eventually

3.4 Test strategy

- fork several threads, and assign different x towards function `waitUntil`
- test whether all the threads waits at least x time and then wake up

4 Communicator

4.1 Design

We need to implement the Communicator() constructor, speak() for speakers and listen() for listeners.

4.2 Variables and functions

For Communicator(), we just need to initialize all the class members.

For listen(), we first acquire a lock, then check whether there is a word ready, if not, wake up a speaker and goes to sleep. When there is a word ready, it receive the word and mark it unread. Finally we release the lock.

For speaker(), we also acquire a lock, check whether there is no listener or whether there is a ready word, if so, we go to sleep. When there is listener and no word ready, we say a word and mark the corresponding flag, wake up all the listener. Finally we release the lock.

Notice that we use a word_ready flag to indicate whether there is a ready word, use num_listener and num_speaker to make the check easier. The wake and sleep operations are realized by two condition variables using the same lock.

4.3 Variables and functions

- num_listener: number of listeners
- num_speaker: number of speakers
- word_ready: indicate whether word is ready
- cond_listener: condition variable for listeners
- cond_speaker: condition variable for speakers
- word: the current word can be heard

4.4 Pseudo-code

Algorithm 8: Communicator::Communicator

```
1 num_listener  $\leftarrow$  0;  
2 num_speaker  $\leftarrow$  0;  
3 word_ready  $\leftarrow$  false;  
4 word  $\leftarrow$  "";  
5 init a lock;  
6 init cond_listener and cond_speaker with the same lock;
```

Algorithm 9: Communicator::speak

```
1 acquire the lock;
2  $num\_speaker \leftarrow num\_speaker + 1$ ;
3 while  $num\_listener$  is 0 or  $word\_ready$  is true do
4   | go to sleep
5  $word \leftarrow$  word of current thread;
6  $word\_ready \leftarrow true$ ;
7 wake all the listeners a listener;
8 sleep;
9  $num\_speaker \leftarrow num\_speaker - 1$ ;
10 release the lock;
```

Algorithm 10: Communicator::listen

```
1 acquire the lock;
2  $num\_listener \leftarrow num\_listener + 1$ ;
3 while  $word\_ready$  is false do
4   | wake up the speaker;
5   | go to sleep
6 get the word;
7  $word\_ready \leftarrow false$ ;
8 wake up all speakers;
9  $num\_listener \leftarrow num\_listener - 1$ ;
10 release the lock
```

4.5 Correctness Constrains

- If there are more than one listener and one speaker, then there will be a thread that are not blocked.
- If a speaker thread finished, then his word is heard and only heard once
- If a listener thread finished, then he heard and only heard a word once

4.6 Test Strategy

- less listener than speaker
- less speaker than listener

For all the above cases, see whether the result is normal

5 Priority scheduling

5.1 Design

To implement the priorityscheduler, we only need to implement the threadstate class and priorityqueue class in priorityscheduler. We set two variables in threadstate: priority and effective. When we want to get priority or effectivepriority, we will return priority and effective. And we set a variable in priorityqueue to record the thread for which the queue is waiting. Then we create an interface setEffectivePriority() to set effective. Every time a new thread add to the queue, it will donate it's priority to it using setEffectivePriority(). Since when a thread's effectivepriority changes, it will affect the priority of the thread it waits, which means it must also call setEffectivePriority() from the threads it waits until the thread doesn't wait. To know what threads it is waiting, we can set a variable in KThread to record the waitqueue the thread is in. Notice that in task 1, if the waitqueue is priorityqueue, it can also donate priority.

5.2 Variables and Functions

- ~~effective~~effective: protected variable in threadstate, save the effective priority of the associated thread.
- waitedthread: public variable in ~~priorityqueue~~priorityQueue, save the thread that the threads in the queue is waiting for.
- waitqueue: private variable in ~~priorityqueue~~priorityQueue, save the waiting thread in priority queue.
- waitingqueue: public variable in KThread, save the queue the thread is in. If the thread doesn't wait for any thread, the waitingqueue should be null.
- threadstate::setEffectivePriority(): When a thread wants to donate priority, it will call this function. We first compare the setting value to the original effective, if it's smaller, do nothing; else, set effective to be the setting value and call seteffectivepriority() in the thread it is waiting for.

- `threadstate::getEffectivePriority()`: It will return the effective priority of the associated thread by returning `effective`.
- `threadstate::waitForAccess()`: When a thread is added to the queue to wait, it will call this function. It will enqueue the thread to `waitqueue` and donate priority to the `waitedthread` by calling `seteffectivepriority` and it will set its `waitingqueue` to the priority queue since it's in it.
- `threadstate::acquire()`: If a thread doesn't need to wait for access in the queue, it will call this function. It will set the `waitedthread` to the current thread. After `waitedthread` is not null, it will not call this function.
- `priorityqueue::nextThread()`: It will return one thread in the queue which has the highest priority. If the queue is empty, it will return null. Since the thread in the queue is now waiting for the return thread, the `waitedthread` is set to the return thread. And the return thread is no longer waiting, the `waitingqueue` is set to null and the effective priority of the previous thread is reset to `priority`.
- `threadstate::resetpriority()`: reset effective priority.

5.3 Pseudo-code

Algorithm 11: `threadstate::setEffectivePriority()`

Input: `priority`

```

1 if priority > effective then
2   effective = priority
3   if thread.waitingqueue.waitedthread ≠ null then
4     getThreadState(thread.waitingqueue.waitedthread).seteffectivepriority(priority)

```

Algorithm 12: `threadstate::getEffectivePriority()`

```

1 return effective

```

Algorithm 13: `threadstate::waitForAccess(waitQueue)`

```

1 waitQueue.add(thisthread)
2 getThreadState(waitQueue.waitedthread).setEffectivePriority(getPriority(this))

3 this->waitingqueue = waitQueue

```

5.4 Correctness constraints

1. The effective priority of a thread is larger than or equal to the effective priority of all the threads which is waiting for it directly or indirectly.

Algorithm 14: priorityqueue::nextThread()

```
1 if waitqueue.isEmpty() then
2   getThreadState(waitedthread).resetpriority()
3   waitedthread = null
4   return null
5 else
6   Find the thread A in waitqueue such that the effective priority is
   highest.(If multiple threads with the same highest priority are
   waiting, choose the one that has been waiting in the queue the
   longest) A.waitingqueue = null
7   getThreadState(waitedthread).resetpriority()
8   waitedthread = A
```

Algorithm 15: threadstate::acquire(waitQueue)

```
1 waitQueue.waitedthread = current current thread
```

5.5 test strategy

1. fork several threads with locks, each thread holds a lock and waits the previous thread's lock, test whether the donation works.
2. fork several threads, set some of them with high priority and some of them with low priority and all waiting for some locks, test whether the threads with high priority will finish first.

6 Boat Grader

6.1 Design

Notice that if we ensure 3 properties below, then all the people will finally get to Molokai:

1. every time, boat to Molokai is full: it will catch 1 adult or 2 children, not only one child.
2. every time, on boat back Oahu, there is only one child.
3. the boat won't stuck: there always appropriate people to put on boat for above two situations.

Brief proof is that: suppose 1 adult is 100kg and 1 child is 50kg, then by properties 1 and 2, there is 50kg weight-down of total weight of Oahu after every round trip, since the boat never stuck, total weight of Oahu will down to 0, i.e. they will finally all get to Molokai.

Algorithm 16: threadstate::resetpriority()

```
1 effective = priority
```

For ensuring above properties, we assume there are at least two children. From above analysis, we find that children play a role piloting boat back Oahu, and adult never return, so we decide to send children first, which is the idea our algorithm design originated.

6.2 Variables and functions

- BoatLocation: Oahu or Molokai;(global variable)
- Location: for each thread, keep in track where the person is;(local variable)
- BoatLock: a lock for protecting action to boat;
- WaitOahu: condition variable based BoatLock, for people waiting on Oahu;
- WaitMolokai: condition variable based BoatLock, for people waiting on Molokai;
- WaitFull: condition variable based BoatLock, for to get two children on boat;
- Weight: weight of people on boat;(50kg for 1 child, 100kg for 1 adult)
- Total: number of all people;(variable for main thread)
- OnMolokai: number of people on Molokai;(variable for main thread)
- ChOahu: number of children on Oahu;(global variable for Oahu people)
- AuOahu: number of adults on Oahu;(for final child decide whether come back)

6.3 Pseudo-code

Algorithm 17: Boat::begin

- 1 fork adult and child threads
 - 2 listen OnMolokai until which equal to Total
-

6.4 Testing

test(0,2,b), (0,10,b) , (10,2,b) , (10,10,b).

7 Test Cases

7.1 Join

The test is called selfTest in file KThread.java. We can just call KThread.selfTest() in ThreadedKernel to run it. selfTest() contains two parts. Ping Test used to

Algorithm 18: Boat::ChildItinerary

```
1 acquire BoatLockrelease BoatLock while true do
2   acquire BoatLock
3   if Location=Oahu then
4     while BoatLocation≠Oahu || Weight= 100 || ChOahu= 1 do
5       WaitOahu.sleep
6     waitOahu.wakeall
7     if Weight= 0 then
8       BOOL fi = (AuOahu= 0 && ChOahu= 2)
9       Weight+ = 50
10      WaitFull.sleep
11      bg.ChildRideToMolokai
12      Location:=Molokai
13      OnMolokai+ = 1
14      if fi=true then
15        WaitMolokai.sleep
16      else
17        Weight+ = 50
18        bg.ChildRowToMolokai
19        WaitFull.wake
20        ChOahu- = 2
21        BoatLocation:=Molokai
22        Location:=Molokai
23        OnMolokai+ = 1
24        Weight- = 100
25        WaitMolokai.sleep
26    else
27      Weight+ = 50
28      OnMolokai- = 1
29      BoatLocation:=Oahu
30      Location:=Oahu
31      Weight- = 50
32      ChOahu+ = 1
33      WaitOahu.wakeall
34  release BoatLock
```

Algorithm 19: Boat::AdultItinerary

```
1 acquire BoatLock
2 if Location=Oahu then
3   while BoatLocation≠Oahu || Weight= 100 || ChOahu> 1 do
4     | WaitOahu.sleep
5   Weight+ = 100
6   AuOahu- = 1
7   bg.AdultRowToMolokai
8   BoatLocation:=Molokai
9   Location:=Molokai
10  OnMolokai+ = 1
11  Weight- = 100
12  WaitMolokai.wakeall
13  WaitMolokai.sleep
14 else
15   | WaitMolokai.sleep
16 release BoatLock
```

see whether it can finally runs normally independently, and Join Test to see whether one thread can wait for the other as expected.

In the function selfTest() we first see whether two threads can yeild to each other for a given times. Then we fork several threads, and see whether they can process as the order indicated by the join command.

7.2 Condition Variable

The test is called selfTest() in file Condition2.java. We can just call Condition2.selfTest() in ThreadedKernel to run it. The purpose is to test whether sleep(), wake() and wakeAll() will function normally.

We just initialize a lock and initialize a condition variable corresponded. New an array of threads using the same lock and condition variable. Then fork all them. In each thread, once they aquire the lock, they just sleep waiting for the condition variable. Then we call wake in the test code, wait to see whether one thread will be woken. Then call wakeAll in the test code, wait to see whether all the threads will be woken.

7.3 Alarm

The test is called selfTest() in file Alarm.java. We can just call Alarm.selfTest() in ThreadedKernel to run it. The purpose is to test whether waitUntil() will function normally.

We just new a runnable thread, where we new an array of threads. We assign different wait time to them, and compare the intended time and the actual time to see whether the formor is less or equal to the latter.

7.4 Communicator

The test is called `selfTest()` in file `Communicator.java`. We can just call `Communicator.selfTest()` in `ThreadedKernel` to run it. The purpose is to test whether `Communicator` will function normally under all kinds of circumstances.

We implemented a function named `Test(s, l)` to test the case when there are `s` speakers and `l` listeners. Then in the `selfTest()` function, we called `Test(3,5)`, `Test(5,3)`, `Test(4,1)`, `Test(1,3)`, `Test(4,4)` to test the cases when there are more speakers than listeners, more listeners than speakers, only 1 speaker, only 1 listener, and equal number of listeners and speakers.

In function `Test(s,l)` we just initialize `s` speaker threads and `l` listener threads, then fork them all one by one. If the speakers are less than listeners, we wait for the speakers to terminate and then exit. Otherwise we wait for the listeners to terminate and then exit.

7.5 Priority Scheduling

1. `selfTest 1`: Fork several threads sleep a long time until the main thread get a lock. Then all the threads will acquire the lock before the main thread release it. So the threads will get the lock following the priority. We can test whether the priority queue works.

2. `selfTest 2,3`: Fork threads with priority 0 to 7 which run a long time. Then we can create some testing thread wait for another thread with different priorities. We can check whether the testing threads finish with the right effective priority (Since threads with priority 0 to 7 running a long time, and we know when it finishes.)

3. `selfTest 4`: let the main thread join the thread 0,1 with priority 0 and 1 when threads 0 and 1 create with different order. Check which threads finish first to test whether the first thread finishes first.

7.6 Boat Grader

Call `Boat.selfTest()` in `ThreadedKernel`:

- `(0,2,b)` is two children case, which is the case with minimal number of people, also should be the final step of every situation.
- `(0,10,b)` is the situation only children, but more than two.
- `(10,2,b)` is the situation with least number of children, and with adults.
- `(10,10,b)` is the situation with many adults and more than two children.

so, by the idea of whether there are adults or not, and whether there are two or more than two children, we get the above 4 cases, which is sufficient.
